

Query Languages for XML

XPath

XQuery

XSLT

The XPath/XQuery Data Model

- ◆ Corresponding to the fundamental “relation” of the relational model is: *sequence of items*.
- ◆ An *item* is either:
 1. A primitive value, e.g., integer or string.
 2. A *node* (defined next).

Principal Kinds of Nodes

1. *Document nodes* represent entire documents.
2. *Elements* are pieces of a document consisting of some opening tag, its matching closing tag (if any), and everything in between.
3. *Attributes* names that are given values inside opening tags.

Document Nodes

- ◆ Formed by `doc(URL)` or `document(URL)`.
- ◆ **Example**: `doc(/usr/class/cs145/bars.xml)`
- ◆ All XPath (and XQuery) queries refer to a doc node, either explicitly or implicitly.
 - ◆ **Example**: key definitions in XML Schema have Xpath expressions that refer to the document described by the schema.

DTD for Running Example

```
<!DOCTYPE BARS [  
  <!ELEMENT BARS (BAR*, LEMONADE*)>  
  <!ELEMENT BAR (PRICE+)>  
    <!ATTLIST BAR name ID #REQUIRED>  
  <!ELEMENT PRICE (#PCDATA)>  
    <!ATTLIST PRICE theLemonade IDREF #REQUIRED>  
  <!ELEMENT LEMONADE EMPTY>  
    <!ATTLIST LEMONADE name ID #REQUIRED>  
    <!ATTLIST LEMONADE soldBy IDREFS #IMPLIED>  
>
```

Example Document

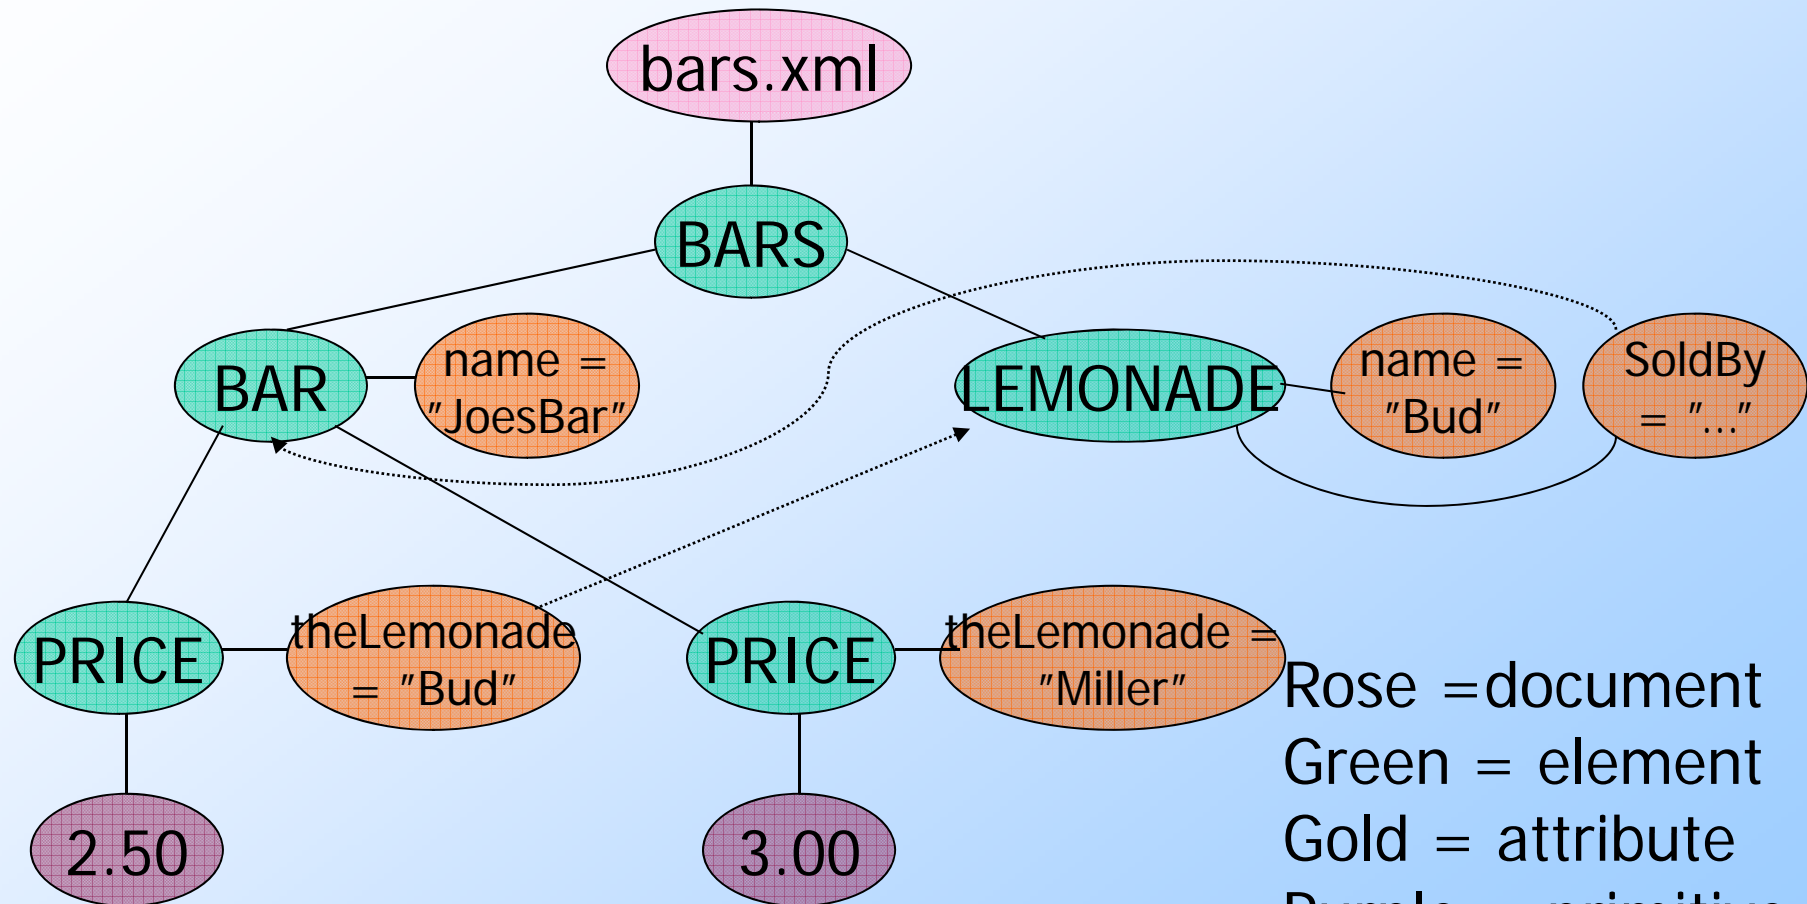

```
<BARS>  
  <BAR name = "JoesBar" >  
    <PRICE theLemonade = "Bud">2.50</PRICE>  
    <PRICE heLemonade = "Miller">3.00</PRICE>  
  </BAR> ...  
<LEMONADE name = "Bud" soldBy = "JoesBar  
  SuesBar ... "/> ...  
</BARS>
```

An element node

An attribute node

Document node is all of this, plus
the header (<? xml version...).

Nodes as Semistructured Data

Rose = document
Green = element
Gold = attribute
Purple = primitive
value

Paths in XML Documents

- ◆ XPath is a language for describing paths in XML documents.
- ◆ The result of the described path is a sequence of items.

Path Expressions

- ◆ Simple path expressions are sequences of slashes (/) and tags, starting with /.
 - ◆ **Example:** /BARS/BAR/PRICE
- ◆ Construct the result by starting with just the doc node and processing each tag from the left.

Evaluating a Path Expression

- ◆ Assume the first tag is the root.
 - ◆ Processing the doc node by this tag results in a sequence consisting of only the root element.
- ◆ Suppose we have a sequence of items, and the next tag is X .
 - ◆ For each item that is an element node, replace the element by the subelements with tag X .

Example: /BARS

```
<BARS>
```

```
  <BAR name = "JoesBar">
```

```
    <PRICE theLemonade = "Bud">2.50</PRICE>
```

```
    <PRICE theLemonade = "Miller">3.00</PRICE>
```

```
  </BAR> ...
```

```
  <LEMONADE name = "Bud" soldBy = "JoesBar
```

```
    SuesBar ... "/> ...
```

```
</BARS>
```

One item, the
BARS element

Example: /BARS/BAR

<BARS>

```
<BAR name = "JoesBar" >
```

```
  <PRICE theLemonade = "Bud" >2.50</PRICE >
```

```
  <PRICE the Lemonade = "Miller" >3.00</PRICE >
```

```
</BAR > ...
```

```
<LEMONADE name = "Bud" soldBy = "JoesBar
```

```
  SuesBar ..."/> ...
```

</BARS>

This BAR element followed by
all the other BAR elements

Example: /BARS/BAR/PRICE

<BARS>

<BAR name = "JoesBar">

<PRICE theLemonade = "Bud">2.50</PRICE>

<PRICE theLemonade = "Miller">3.00</PRICE>

</BAR> ...

<LEMONADE name = "Bud" soldBy = "JoesBar
SuesBar ..."/>...

</BARS>

These PRICE elements followed
by the PRICE elements
of all the other bars.

Attributes in Paths

- ◆ Instead of going to subelements with a given tag, you can go to an attribute of the elements you already have.
- ◆ An attribute is indicated by putting @ in front of its name.

Example: /BARS/BAR/PRICE/@ theLemonade

<BARS>

<BAR name = "JoesBar" >

<PRICE theLemonade = "Bud" >2.50</PRICE>

<PRICE theLemonade = "Miller" >3.00</PRICE>

</BAR> ...

<LEMONADE name = "Bud" soldBy = "JoesBar

SuesBar ..."/> ...

</BARS>

These attributes contribute "Bud" "Miller" to the result, followed by other theLemonade values.

Remember: Item Sequences

- ◆ Until now, all item sequences have been sequences of elements.
- ◆ When a path expression ends in an attribute, the result is typically a sequence of values of primitive type, such as strings in the previous example.

Paths that Begin Anywhere

- ◆ If the path starts from the document node and begins with `//X`, then the first step can begin at the root or any subelement of the root, as long as the tag is `X`.

Example: //PRICE

<BARS>

<BAR name = "JoesBar">

<PRICE theLemonade = "Bud">2.50</PRICE>

<PRICE theLemonade = "Miller">3.00</PRICE>

</BAR> ...

<LEMONADE name = "Bud" soldBy = "JoesBar

SuesBar ..."/> ...

</BARS>

These PRICE elements and any other PRICE elements in the entire document

Wild-Card *

- ◆ A star (*) in place of a tag represents any one tag.
- ◆ **Example:** /*/*/PRICE represents all price objects at the third level of nesting.

Example: /BARS/*

This BAR element, all other BAR elements, the LEMONADE element, all other LEMONADE elements

<BARS>

<BAR name = "JoesBar" >

<PRICE theLemonade = "Bud" >2.50</PRICE>

<PRICE theLemonade = "Miller" >3.00</PRICE>

</BAR> ...

<LEMONADE name = "Bud" soldBy = "JoesBar

SuesBar ... "/> ...

</BARS>

Selection Conditions

- ◆ A condition inside [...] may follow a tag.
- ◆ If so, then only paths that have that tag and also satisfy the condition are included in the result of a path expression.

Example: Selection Condition

◆ /BARS/BAR/PRICE[< 2.75]

<BARS>

<BAR name = "JoesBar">

<PRICE theLemonade = "Bud">2.50</PRICE>

<PRICE theLemonade = "Miller">3.00</PRICE>

</BAR> ...

The current element.

The condition that the PRICE be < \$2.75 makes this price but not the Miller price part of the result.

Example: Attribute in Selection

◆ /BARS/BAR/PRICE[@ theLemonade = "Miller"]

<BARS>

<BAR name = "JoesBar" >

<PRICE theLemonade = "Bud" >2.50</PRICE>

<PRICE theLemonade = "Miller" >3.00</PRICE>

</BAR> ...

Now, this PRICE element is selected, along with any other prices for Miller.

XQuery

- ◆ XQuery extends XPath to a query language that has power similar to SQL.
- ◆ Uses the same sequence-of-items data model.
- ◆ XQuery is an expression language.
 - ◆ Like relational algebra --- any XQuery expression can be an argument of any other XQuery expression.

More About Item Sequences

- ◆ XQuery will sometimes form sequences of sequences.
- ◆ All sequences are flattened.
- ◆ **Example:** $(1\ 2\ ()\ (3\ 4)) = (1\ 2\ 3\ 4)$.

FLWR Expressions

1. One or more **for** and/or **let** clauses.
2. Then an optional **where** clause.
3. A **return** clause.

Semantics of FLWR Expressions

- ◆ Each **for** creates a loop.
 - ◆ **let** produces only a local definition.
- ◆ At each iteration of the nested loops, if any, evaluate the **where** clause.
- ◆ If the **where** clause returns TRUE, invoke the **return** clause, and append its value to the output.

FOR Clauses

for <variable> in <expression>, . . .

- ◆ Variables begin with \$.
- ◆ A **for**-variable takes on each item in the sequence denoted by the expression, in turn.
- ◆ Whatever follows this **for** is executed once for each value of the variable.

Our example
BARS document

Example: FOR

"Expand the enclosed string by replacing variables and path exps. by their values."

for \$lemonade in
document("bars.xml")/BARS/LEMONADE/@name

return

<LEMONADENAME> {\$lemonade} </LEMONADENAME>

◆ \$lemonade ranges over the name attributes of all lemonades in our example document.

◆ Result is a sequence of LEMONADENAME elements:

< LEMONADENAME > Bud </LEMONADENAME >

< LEMONADENAME > Miller </LEMONADENAME > . . .

Use of Braces

- ◆ When a variable name like `$x`, or an expression, could be text, we need to surround it by braces to avoid having it interpreted literally.
 - ◆ **Example:** `<A>$x` is an A-element with value "`$x`", just like `<A>foo` is an A-element with "`foo`" as value.

Use of Braces --- (2)

- ◆ But `return $x` is unambiguous.
- ◆ You cannot return an untagged string without quoting it, as `return "$x"`.

LET Clauses

let <variable> := <expression>, . . .

- ◆ Value of the variable becomes the *sequence* of items defined by the expression.
- ◆ Note **let** does not cause iteration; **for** does.

Example: LET

```
let $d := document("bars.xml")
```

```
let $lemonades := $d/BARS/LEMONADE/@name
```

```
return
```

```
<LEMONADENAMES>{$lemonades}</LEMONADENAMES>
```

◆ Returns one element with all the names of the lemonades, like:

```
<LEMONADENAMES>Bud Miller ...</LEMONADENAMES>
```

Order-By Clauses

- ◆ FLWR is really FLWOR: an order-by clause can precede the return.
- ◆ Form: order by <expression>
 - ◆ With optional **ascending** or **descending**.
- ◆ The expression is evaluated for each assignment to variables.
- ◆ Determines placement in output sequence.

Example: Order-By

- ◆ List all prices for Bud, lowest first.

```
let $d := document("bars.xml")
```

```
for $p in  
  $d/BARS/BAR/PRICE[@theLemonade="Bud"]
```

```
order by $p
```

```
return $p
```

Each binding is evaluated for the output. The result is a sequence of PRICE elements.

Order those bindings by the values inside the elements (automatic coercion).

Generates bindings for \$p to PRICE elements.

Aside: SQL ORDER BY

- ◆ SQL works the same way; it's the result of the FROM and WHERE that get ordered, not the output.

- ◆ **Example:** Using $R(a,b)$,

```
SELECT b FROM R
```

```
WHERE b > 10
```

```
ORDER BY a;
```

Then, the b-values are extracted from these tuples and printed in the same order.

R tuples with $b > 10$ are ordered by their a-values.

Predicates

- ◆ Normally, conditions imply existential quantification.
- ◆ **Example:** /BARS/BAR[@name] means "all the bars that have a name."
- ◆ **Example:** /BARS/LEMONADE[@soldAt = "JoesBar"] gives the set of lemonades that are sold at Joe's Bar.

Example: Comparisons

- ◆ Let us produce the PRICE elements (from all bars) for all the lemonades that are sold by Joe's Bar.
- ◆ The output will be BLP elements with the names of the bar and lemonade as attributes and the price element as a subelement.

Strategy

1. Create a triple for-loop, with variables ranging over all LEMONADE elements, all BAR elements, and all PRICE elements within those BAR elements.
2. Check that the lemonade is sold at Joe's Bar and that the name of the lemonade and **theLemonade** in the PRICE element match.
3. Construct the output element.

The Query

```
let $bars = doc("bars.xml")/BARS
for $lemonade in $bars/LEMONADE
for $bar in $bars/BAR
for $price in $bar/PRICE
where $lemonade/@soldAt = "JoesBar" and
    $price/@theLemonade = $lemonade/@name
return <BLP bar = {$bar/@name} lemonade =
    {$lemonade/@name}>{$price}</BLP>
```

True if "JoesBar"
appears anywhere
in the sequence

Strict Comparisons

- ◆ To require that the things being compared are sequences of only one element, use the Fortran comparison operators:
 - ◆ eq, ne, lt, le, gt, ge.
- ◆ **Example:** `$lemonade/@soldAt eq "JoesBar"` is true only if Joe's is the only bar selling the lemonade.

Comparison of Elements and Values

- ◆ When an element is compared to a primitive value, the element is treated as its value, if that value is atomic.

- ◆ **Example:**

```
/BARS/BAR[@name="JoesBar"]/
```

```
PRICE[@theLemonade="Bud"] eq "2.50"
```

is true if Joe charges \$2.50 for Bud.

Comparison of Two Elements

◆ It is insufficient that two elements look alike.

◆ **Example:**

```
/BARS/BAR[@name="JoesBar"]/
```

```
PRICE[@theLemonade="Bud"] eq
```

```
/BARS/BAR[@name="SuesBar"]/
```

```
PRICE[@theLemonade="Bud"]
```

is false, even if Joe and Sue charge the same for Bud.

Comparison of Elements – (2)

- ◆ For elements to be equal, they must be the same, physically, in the implied document.
- ◆ **Subtlety**: elements are really pointers to sections of particular documents, not the text strings appearing in the section.

Getting Data From Elements

- ◆ Suppose we want to compare the values of elements, rather than their location in documents.
- ◆ To extract just the value (e.g., the price itself) from an element E , use `data(E)`.

Example: data()

- ◆ Suppose we want to modify the return for “find the prices of lemonades at bars that sell a lemonade Joe sells” to produce an empty BLP element with price as one of its attributes.

```
return <BLP bar = {$bar/@name}  
lemonade = {$lemonade/@name}  
price = {data($price)} />
```

Eliminating Duplicates

- ◆ Use function `distinct-values` applied to a sequence.
- ◆ **Subtlety**: this function strips tags away from elements and compares the string values.
 - ◆ But it doesn't restore the tags in the result.

Example: All the Distinct Prices

```
return distinct-values(
```

```
  let $bars = doc("bars.xml")  
  return $bars/BARS/BAR/PRICE
```

```
)
```

Remember: XQuery is
an expression language.
A query can appear any
place a value can.

Effective Boolean Values

- ◆ The *effective boolean value* (EBV) of an expression is:
 1. The actual value if the expression is of type boolean.
 2. FALSE if the expression evaluates to 0, "" [the empty string], or () [the empty sequence].
 3. TRUE otherwise.

EBV Examples

1. `@name="JoesBar"` has EBV TRUE or FALSE, depending on whether the name attribute is "JoesBar".
2. `/BARS/BAR[@name="GoldenRail"]` has EBV TRUE if some bar is named the Golden Rail, and FALSE if there is no such bar.

Boolean Operators

- ◆ E_1 and E_2 , E_1 or E_2 , $\text{not}(E)$, apply to any expressions.
- ◆ Take EBV's of the expressions first.
- ◆ **Example**: $\text{not}(3 \text{ eq } 5 \text{ or } 0)$ has value TRUE.
- ◆ Also: $\text{true}()$ and $\text{false}()$ are functions that return values TRUE and FALSE.

Branching Expressions

- ◆ if (E_1) then E_2 else E_3 is evaluated by:
 - ◆ Compute the EBV of E_1 .
 - ◆ If true, the result is E_2 ; else the result is E_3 .
- ◆ **Example:** the PRICE subelements of \$bar, provided that bar is Joe's.

```
if ($bar/@name eq "JoesBar" )  
then $bar/PRICE else 
```

Empty sequence. Note there is no if-then expression.

Quantifier Expressions

some x in E_1 satisfies E_2

1. Evaluate the sequence E_1 .
2. Let x (any variable) be each item in the sequence, and evaluate E_2 .
3. Return TRUE if E_2 has EBV TRUE for at least one x .

◆ Analogously:

every x in E_1 satisfies E_2

Example: Some

- ◆ The bars that sell at least one lemonade for less than \$2.

```
for $bar in
```

```
  doc( "bars.xml" ) / BARS / BAR
```

```
  where some $p in $bar/PRICE  
    satisfies $p < 2.00
```

```
  return $bar/@name
```

Notice: where \$bar/PRICE < 2.00
would work as well.

Example: Every

- ◆ The bars that sell no lemonade for more than \$5.

```
for $bar in
```

```
    doc( "bars.xml" ) / BARS / BAR
```

```
where every $p in $bar / PRICE
```

```
    satisfies $p <= 5.00
```

```
return $bar / @name
```

Document Order

◆ Comparison by document order: $<<$ and $>>$.

◆ **Example:**

$\$d/\text{BARS}/\text{LEMONADE}[@\text{name}=\text{"Bud"}] <<$
 $\$d/\text{BARS}/ \text{LEMONADE}[@\text{name}=\text{"Miller"}]$ is
true iff the Bud element appears before
the Miller element in the document $\$d$.

Set Operators

- ◆ **union, intersect, except** operate on sequences of nodes.
 - ◆ Meanings analogous to SQL.
 - ◆ Result eliminates duplicates.
 - ◆ Result appears in document order.

XSLT

- ◆ XSLT (*extensible stylesheet language – transforms*) is another language to process XML documents.
- ◆ Originally intended as a presentation language: transform XML into an HTML page that could be displayed.
- ◆ It can also transform XML -> XML, thus serving as a query language.

XSLT Programs

- ◆ Like XML Schema, an XSLT program is itself an XML document.
- ◆ XSLT has a special namespace of tags, usually indicated by **xsl:**.

Templates

- ◆ The `xsl:template` element describes a set of elements (of the document being processed) and what should be done with them.
- ◆ The form: `<xsl:template match = path >`
... `</xsl:template>`

Attribute match gives an XPath expression describing how to find the nodes to which the template applies.

Example: BARS Document -> Table

- ◆ In a running example, we'll convert the `bars.xml` document into an HTML document that looks like the `Sells(bar, lemonade, price)` relation.
- ◆ The first template will match the root of the document and produce the table without any rows.

The Template for the Root

```
<xsl:template match = "/" />
```

Template matches only the root.

```
<TABLE><TR>  
  <TH>bar</th><TH>lemonade</th>  
  <TH>price</th></tr>  
</table>
```

```
</xsl:template>
```

Needs to be fixed. As is, there is no way to insert rows.

Output of the template is a table with the attributes in the header row, no other rows.

Outline of Strategy

1. Inside the HTML for the table is `xsl:apply-templates` to extract data from the document.
2. From each BAR, use an `xsl:variable` *b* to remember the bar name.
3. `xsl:for-each` PRICE subelement, generate a row, using *b*, and `xsl:value-of` to extract the lemonade name and price.

Recursive Use of Templates

- ◆ An XSLT document usually contains many templates.
- ◆ Start by finding the first one that applies to the root.
- ◆ Any template can have within it `<xsl:apply-templates/>`, which causes the template-matching to apply recursively from the current node.

Apply-Templates

- ◆ Attribute **select** gives an XPath expression describing the subelements to which we apply templates.
- ◆ **Example**: `<xsl:apply-templates select = "BARS/BAR" />` says to follow all paths tagged BARS, BAR from the current node and apply all templates there.

Example: Apply-Templates

```
<xsl:template match = "/">
  <TABLE><TR>
    <TH>bar</th><TH>lemonade</th>
    <TH>price</th></tr>
  <xsl:apply-templates select =
    "BARS" />
</table>
</xsl:template>
```

Extracting Values

- ◆ `<xsl:value-of select = XPath expression />` produces a value to be placed in the output.
- ◆ **Example:** suppose we are applying a template at a BAR element and want to put the bar name into a table.

```
<xsl:value-of select = "@name" />
```

Variables

- ◆ We can declare `x` to be a variable with `<xsl:variable name = "x" />`.

- ◆ **Example:**

```
<xsl:variable name = "bar">  
  <xsl:value-of select = "@name" />  
</xsl:variable>
```

within a template that applies to BAR elements will set variable `bar` to the name of that bar.

Using Variables

- ◆ Put a \$ in front of the variable name.
- ◆ **Example:** `<TD>$bar</td>`

Completing the Table

1. We'll apply a template at each BAR element.
2. This template will assign a variable **b** the value of the bar, and iterate over each PRICE child.
3. For each PRICE child, we print a row, using **i**, the **theLemonade** attribute, and the PRICE itself.

Iteration

◆ `<xsl:for-each select = Xpath expression >`

...

`</xsl:for-each >`

executes the body of the for-each at each child of the current node that is reached by the path.

A variable
for each
bar

The Template for BARS

```
<xsl:template match = "BAR">
```

```
<xsl:variable name = "b">  
  <xsl:value-of select = "@name" />  
</xsl:variable>
```

Constructs a bar-
lemonade-price row.

```
<xsl:for-each select = "PRICE">
```

```
<TR><TD>${b}</td><TD>  
  <xsl:value-of select = "@theLemonade" />  
</td><TD>  
  <xsl:value-of select = "data(.)" />  
</td></tr>
```

```
</xsl:for-each>
```

```
</xsl:template>
```

Iterates over all
PRICE subelements
of the bar.

This
element
